Vanishing of the negative-sign problem of quantum Monte Carlo simulations in one-dimensional frustrated spin systems

(February 7, 2008)

The negative-sign problem in one-dimensional frustrated quantum spin systems is solved. We can remove negative signs of the local Boltzmann weights by using a dimer basis that has the spin-reversal symmetry. Validity of this new basis is checked in a general frustrated double-spin-chain system, namely the J_0-J_1-J_2-J_3 model. The negative sign vanishes perfectly for $J_0 + J_1 \leq J_3$.

arXiv:cond-mat/9707019v1 2 Jul 1997

The class of low-dimensional quantum spin systems is now enjoying a revival of interest both theoretically and experimentally. This recent interest originates in the possibility of the superconductivity upon doping a carrier to an insulator that has a spin gap above the ground state. Spin-ladder models, or more generally double-spin-chain models, are known as such candidates. [1] Syntheses of various corresponding materials [2–4] support the progress of this field under the cooperations between the experiment and the theory. For example, magnetic susceptibility measurements on $KCuCl_3$ [3] and on CaV_2O_5 [4] indicate a spin gap behavior. These systems are considered to be explained by a frustrated double-spin-chain model, and the strength of each interaction bond can be estimated by comparing the experimental data with the theoretical ones. [5] In such analyses, we must calculate the observable quantities for given interaction bonds. This is generally a very difficult task.

Numerical investigations may serve as a powerful tool of calculating the thermodynamic quantities, unless the problem is solved exactly. For example, we can obtain all the eigenvalues of a finite system by the numerical diagonalization. Then any quantity at any temperature is calculated, but the size of the system is very restricted; up to 16 or 18 of $S = 1/2$ spin sites. The quantum Monte Carlo (QMC) method can handle much larger systems, if there is no frustration. [6] Contrary to this, the sampling ruins at low temperatures by the negative-sign problem in the frustrated systems. The transition probability may take a negative value in this situation. One uses its absolute value for the update, and then reweights both the number of steps and the physical quantity in order to obtain the correct value. The problem is caused by the fact that the partition function defined by the absolute values of the local weights is far from the original one, and thus it becomes serious exponentially with the product of the inverse temperature β and the system size N. We are necessary to overcome this negative-sign problem in order to get meaningful numerical data that can be compared directly with the experiment. This is the main subject of this letter.

There have been already proposed several techniques that relax the sign problem: the auxiliary field method, [7] the transfer-matrix Monte Carlo method, [8] the reweighting method, [9] and the restructuring method. [10] However, it remains. Therefore, at low temperatures or for large system sizes, the QMC samplings any way break down.

In this letter we demonstrate that the negative-sign problem is *totally* removed for the first time in the non-trivial frustrated spin systems. The key idea is an extension of the restructuring method, [10] combined with the spin-reversal symmetry that the system usually possesses.

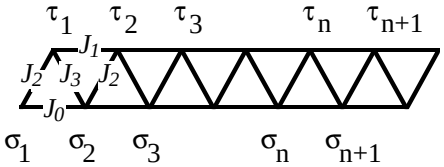

FIG. 1. Shape of the general double-spin-chain model we treat in this letter.

We consider the generalized double-spin-chain system defined by its next-nearest-neighbor interactions, J_0 and J_1, and by the alternating nearest-neighbor interactions, J_2 and J_3, as depicted in Fig. 1. This model can describe various systems; it is reduced to the Majumdar-Ghosh model [11] with a choice of the parameter set $(J_0, J_1, J_2, J_3) = (0.5, 0.5, 1, 1)$. The dimer-fluid transition point, where the spin-Peierls material $CuGeO_3$ [12] is suggested to realize, [13,14] is $(J_0, J_1, J_2, J_3) = (0.2411, 0.2411, 1, 1)$. [15]

We divide the above Hamiltonian into two parts for the Suzuki-Trotter decomposition.

$$\mathcal{H}_1 = \sum_{n=1}^{(N+1)/2} h_{2n-1}, \quad \mathcal{H}_2 = \sum_{n=1}^{N/2} h_{2n} \tag{1}$$

$$h_n = J_0 \boldsymbol{\sigma}_n \cdot \boldsymbol{\sigma}_{n+1} + J_1 \boldsymbol{\tau}_n \cdot \boldsymbol{\tau}_{n+1} + \frac{J_2}{2} \boldsymbol{\sigma}_n \cdot \boldsymbol{\tau}_n + \frac{J_2}{2} \boldsymbol{\sigma}_{n+1} \cdot \boldsymbol{\tau}_{n+1} + J_3 \boldsymbol{\tau}_n \cdot \boldsymbol{\sigma}_{n+1}, \tag{2}$$

Then, the total Boltzmann weight, $\langle\psi| \exp[-\beta\mathcal{H}] |\psi\rangle$, is decomposed into the product of the local weights as

$\langle\psi|e^{-\beta\mathcal{H}}|\psi\rangle = \langle\psi|[e^{-\frac{\beta}{m}\mathcal{H}_1}e^{-\frac{\beta}{m}\mathcal{H}_2}]^m|\psi\rangle$.

We propose the representation basis $|\psi\rangle$ in the following way. Usually, s^z diagonal representation of each spin is chosen for $|\psi\rangle$. Here, we couple two spins, $\boldsymbol{\sigma}_n$ and $\boldsymbol{\tau}_n$, and consider these two spins as an unit. This dimer unit takes four states associated with the s^z eigenvalues of each spin, $|\sigma^z, \tau^z\rangle$. We restructure these four states so that they become eigenstates of the spin-reversal operation R:

$$v_1 = (|\uparrow,\uparrow\rangle + |\downarrow,\downarrow\rangle)/\sqrt{2}, \tag{3}$$

$$v_2 = (|\uparrow,\uparrow\rangle - |\downarrow,\downarrow\rangle)/\sqrt{2}, \tag{4}$$

$$v_3 = (|\uparrow,\downarrow\rangle + |\downarrow,\uparrow\rangle)/\sqrt{2}, \tag{5}$$

$$v_4 = (|\uparrow,\downarrow\rangle - |\downarrow,\uparrow\rangle)/\sqrt{2}. \tag{6}$$

Here, $\uparrow$ and $\downarrow$ denote the s^z eigenstates. Direct product of these four states spans the whole phase space. In this new basis, three interaction bonds, J_0, J_1 and J_3 become a single effective bond connecting the neighboring dimer units, and the J_2 bonds only contribute to the inner energy of the dimer units. It is quite striking that this basis transformation alone removes the negative-sign problem. Let us call this basis 'dimer-R' basis hereafter for simplicity.

In order to calculate the local plaquette Boltzmann weight, $\langle v_i, v_j|\exp[-\beta h_n/m]|v_i', v_j'\rangle$, we need a matrix of the local Hamiltonian, $\langle v_i, v_j|h_n|v_i', v_j'\rangle$. Since the Trotter slice β/m should be small, the sign of the local Boltzmann weight is known from the sign of the local Hamiltonian as $\exp[-\beta h_n/m] \simeq 1 - \beta h_n/m$. Thus we first write down the matrix element of h_n. This 16×16 square matrix is block-diagonalized by the spin-reversal symmetry into four 4×4 sub-blocks:

$$\begin{array}{c} \\ \langle v_1,v_1| \\ \langle v_2,v_2| \\ \langle v_3,v_3| \\ \langle v_4,v_4| \end{array} \begin{array}{c} \begin{array}{cccc} |v_1,v_1\rangle & |v_2,v_2\rangle & |v_3,v_3\rangle & |v_4,v_4\rangle \end{array} \\ \begin{pmatrix} -J_2 & -a & -a & -d \\ -a & -J_2 & a & d \\ -a & a & -J_2 & d \\ -d & d & d & 3J_2 \end{pmatrix} \end{array} \times \frac{-1}{4},$$

$$\begin{array}{c} \\ \langle v_2,v_1| \\ \langle v_1,v_2| \\ \langle v_3,v_4| \\ \langle v_4,v_3| \end{array} \begin{array}{c} \begin{array}{cccc} |v_2,v_1\rangle & |v_1,v_2\rangle & |v_3,v_4\rangle & |v_4,v_3\rangle \end{array} \\ \begin{pmatrix} -J_2 & -a & -b & -c \\ -a & -J_2 & b & c \\ -b & b & J_2 & d \\ -c & c & d & J_2 \end{pmatrix} \end{array} \times \frac{-1}{4},$$

$$\begin{array}{c} \\ \langle v_1,v_3| \\ \langle v_3,v_1| \\ \langle v_2,v_4| \\ \langle v_4,v_2| \end{array} \begin{array}{c} \begin{array}{cccc} |v_1,v_3\rangle & |v_3,v_1\rangle & |v_2,v_4\rangle & |v_4,v_2\rangle \end{array} \\ \begin{pmatrix} -J_2 & -a & -b & -c \\ -a & -J_2 & b & c \\ -b & b & J_2 & d \\ -c & c & d & J_2 \end{pmatrix} \end{array} \times \frac{-1}{4},$$

$$\begin{array}{c} \\ \langle v_2,v_3| \\ \langle v_3,v_2| \\ \langle v_1,v_4| \\ \langle v_4,v_1| \end{array} \begin{array}{c} \begin{array}{cccc} |v_2,v_3\rangle & |v_3,v_2\rangle & |v_1,v_4\rangle & |v_4,v_1\rangle \end{array} \\ \begin{pmatrix} -J_2 & -a & -b & -c \\ -a & -J_2 & b & c \\ -b & b & J_2 & d \\ -c & c & d & J_2 \end{pmatrix} \end{array} \times \frac{-1}{4},$$

where $a = J_0+J_1+J_3$, $b = -J_0+J_1+J_3$, $c = J_0-J_1+J_3$, and $d = -J_0-J_1+J_3$.

These matrix elements include negative signs and it seems that the negative-sign problem exists. However, we can remove the negative sign by the following nonlocal unitary transformation. [16–18] This transformation is an adaptation of the Kennedy-Tasaki transformation [16] of the $S = 1$ AF Heisenberg chain to the $S = 1/2$ double-spin-chain systems. It is defined by U:

$$U = \prod_{n=1}^{N} P_n^+ + P_n^- \exp[i\pi S_n^x], \tag{7}$$

$$P_n^{\pm} = \frac{1}{2}\left(1 \pm \exp\left[i\pi \sum_{k=1}^{n-1} S_k^z\right]\right), \tag{8}$$

where $\boldsymbol{S}_n = \boldsymbol{\sigma}_n + \boldsymbol{\tau}_n$. Then, the local Hamiltonian h_n is transformed as,

$$\begin{aligned} U^{-1}h_nU = {} & J_0(-\sigma_n^x\tau_{n+1}^x - \tau_n^z\sigma_{n+1}^z - 4\sigma_n^x\tau_{n+1}^x\tau_n^z\sigma_{n+1}^z) \\ & + J_1(-\tau_n^x\sigma_{n+1}^x - \sigma_n^z\tau_{n+1}^z - 4\tau_n^x\sigma_{n+1}^x\sigma_n^z\tau_{n+1}^z) \\ & + J_3(-\tau_n^x\tau_{n+1}^x - \sigma_n^z\sigma_{n+1}^z - 4\tau_n^x\tau_{n+1}^x\sigma_n^z\sigma_{n+1}^z) \\ & + \frac{J_2}{2}\boldsymbol{\sigma}_n\cdot\boldsymbol{\tau}_n + \frac{J_2}{2}\boldsymbol{\sigma}_{n+1}\cdot\boldsymbol{\tau}_{n+1}. \end{aligned} \tag{9}$$

Each matrix element of this transformed Hamiltonian becomes the one whose negative sign is taken away from the original one. Note that the signs of the interactions, J_0, J_1, and J_3 are changed. All the matrix elements become positive if all the a, b, c, and d are positive. This is when

$$d = -J_0 - J_1 + J_3 \geq 0, \tag{10}$$

for the AF positive values of J_0, J_1 and J_3. This condition includes various interesting models as stated before. The above condition does not restrict the value of J_2, since it only contributes to the diagonal matrix elements. We can now perform quantum Monte Carlo simulations without the negative-sign problem. Before the demonstration of the numerical results, we point out several important notices.

Since we have removed the negative-sign problem by using the spin-reversal symmetry, we have to be careful about the operation that breaks this symmetry. For example, the negative-sign problem appears again, if we apply the uniform magnetic field. In our new representation, the matrix element for the uniform magnetic field H only takes a value between v_1 and v_2, i.e., $\langle v_1| - HS_i^z|v_2\rangle = -H$, for $S_i^z = \sigma_i^z + \tau_i^z$. Thus this term has a value in the off-block-diagonal part.

Another point is that we cannot observe the uniform magnetic susceptibility from the fluctuation of the magnetization, since it does not fluctuate but always remains zero. In other words, a local expectation value of the magnetization, $\langle v_i, v_j|(S_1^z+S_2^z)\exp[-\beta h_1/m]|v_i', v_j'\rangle$, vanishes for a non-vanishing Boltzmann weight, and vice versa. Therefore, we have considered the following two different methods of calculating the susceptibility. Both methods intrinsically suffer the negative-sign problem, but, it is not so severe that we can obtain sufficient data for the large system sizes at low temperatures.

The first one is that we take all the configurational summation over a single Trotter layer ψ' to deduce the expectation value of $\langle\psi|(\sum_i S_i^z)^2\exp[-\beta H_1/m]|\psi'\rangle$ in the measurement stage at each Monte Carlo step. That is, we take a Monte Carlo summation of

$$\frac{\sum_{\psi_1'}\langle\psi_0|(\sum_i S_i^z)^2 e^{-\beta\mathcal{H}_1/m}|\psi_1'\rangle\langle\psi_1'|e^{-\beta\mathcal{H}_2/m}|\psi_2\rangle}{\langle\psi_0|e^{-\beta\mathcal{H}_1/m}|\psi_1\rangle\langle\psi_1|e^{-\beta\mathcal{H}_2/m}|\psi_2\rangle} \quad (11)$$

as a contribution to the numerator of the susceptibility. Here, ψ_0, ψ_1, and ψ_2 are the states that are actually realized in the simulation, and ψ_1' is the virtual state that should be traced out. This tracing-out can be done by multiplying a 4×4 transfer matrix along the real space direction. The contribution to the denominator,

$$\frac{\sum_{\psi_1'}\langle\psi_0|e^{-\beta\mathcal{H}_1/m}|\psi_1'\rangle\langle\psi_1'|e^{-\beta\mathcal{H}_2/m}|\psi_2\rangle}{\langle\psi_0|e^{-\beta\mathcal{H}_1/m}|\psi_1\rangle\langle\psi_1|e^{-\beta\mathcal{H}_2/m}|\psi_2\rangle}, \quad (12)$$

always becomes unity by the conservation law of the spin-reversal eigenvalue and thus it becomes the number of steps. This way of calculating the susceptibility gives the correct values with sufficiently small error bars especially at rather high temperatures. The sampling suddenly becomes worse at low temperatures in larger sizes. This is because we simulate the full system and observe the susceptibility in the system that a single layer is traced out. Since both systems are different from each other by one Trotter layer, there should exist the negative-sign problem. This appears in both the numerator and the denominator of Eq. (11), which can take both a positive and a negative sign.

The other method is the numerical differentiation of the magnetization when we apply the sufficiently small magnetic field. As discussed above, the negative-sign problem appears under the magnetic field, however, the problem is not so serious if it is small enough. For example, the typical negative-sign ratio at the temperature $T/J_2 = 0.04$ is only 0.5 with the field $H/J_2 = 0.02$ in the system with 34 spins. Thus we can calculate the susceptibility without any difficulty.

Now that we show the numerical results and demonstrate the usefulness of the present new basis. We set the interaction bonds $J_0 = J_1$ and $J_2 = J_3$ with $J_1/J_2 = 0.2411$, so that this system is at the dimer-fluid transition point. We first check our simulation giving a correct values by comparing with the exact results obtained by the numerical diagonalization in the system with 10 spins. Then we show the results of 34 spins, which cannot be achieved by any other method. The boundary conditions are set open. The temperatures that we actually ran simulations are pointed by arrows in Fig. 2 and Fig. 3. The others are estimated by the reweighting method. [9] We have done the Trotter extrapolations by using five or six different Trotter numbers ranging from $\beta/m = 0.5$ to about 0.2. The number of the Monte Carlo steps is typically five millions divided into ten parts to estimate the deviations. The correlation time for the energy is about 5 steps for $T/J_2 = 0.2$ and $m = 24$; that for the susceptibility obtained by the transfer matrix as mentioned above is about 1 step.

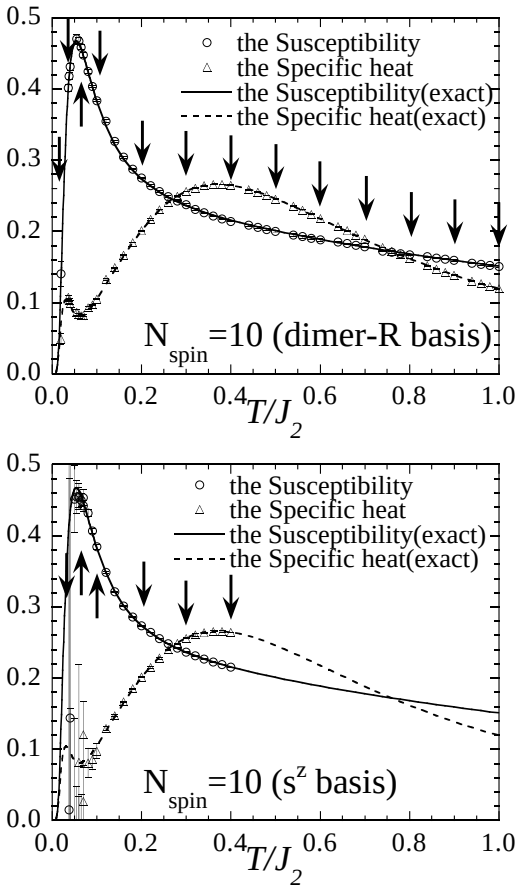

FIG. 2. (a) The susceptibility (circles) and the specific heat (triangles) for the system with 10 spins calculated by using the present dimer-R basis. The exact results obtained by the numerical diagonalization are denoted by lines. (b) Those for the same system as (a) but calculated by using the conventional s^z basis. Arrows indicate the temperatures that the simulations are actually performed. The others are estimated by the reweighting method.

Figure 2 (a) shows the susceptibility and the specific heat for the system with 10 spins calculated by using

the present dimer-R basis; (b) shows the results for the same system calculated by the same program but only the representation basis is different using the conventional s^z one. The exact results obtained by the numerical diagonalization are plotted by lines. Agreements of the data in Fig. 2 (a) with the exact values are very excellent down to the temperature $T/J_2 = 0.02$ for both quantities. Error bars are mostly as small as invisible. We calculated the susceptibility here by using the transfer matrix described above as the first method. Since the system size is small enough, the instability of the data due to the tracing-out of one layer scarcely occurred. On the other hand, the samplings of the s^z basis crashes already at $T/J_2 = 0.1$. This means that the QMC method cannot be applied even in a small system that can be fully diagonalized numerically, once one uses the conventional s^z basis.

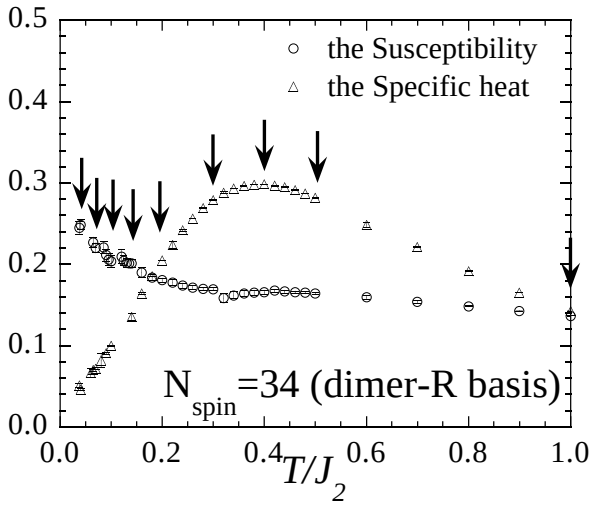

FIG. 3. The susceptibility (circles) and the specific heat (triangles) for the system with 34 spins calculated by using the present dimer-R basis. Arrows indicate the temperatures that the simulations are actually performed.

Figure 3 shows the results for the system with 34 spins. The susceptibility was calculated by the transfer matrix for the data of $T/J_2 \geq 0.2$, and by the numerical differentiation of the magnetization for those of $T/J_2 < 0.2$. Both methods give consistent results within the error bars, and we have selected the one whose error bar is smaller than the other one. The magnitude of the uniform magnetic field for the latter case is $H/J_2 = 0.02$. The susceptibility grows as decreasing the temperature, i.e., the pseudo gap caused by the finite size of the system seems to be much smaller than the temperature range we simulated. The specific heat was calculated in the simulation with zero field. The error bars for this value is also negligible. Rather large ones, though they are within the symbols, are solely from the reweighting error. Thus, there is no difficulty in calculating the response functions of the operators that conserve the spin-reversal symmetry. We consider that the temperature can be lowered from $T/J_2 = 0.04$, if one can have much more CPU time to handle the simulations with large Trotter number.

We have presented a new possibility of the quantum Monte Carlo method by using the representation basis that has the spin-reversal symmetry. The negative-sign problem is totally removed in the wide range of the parameter space of the one-dimensional frustrated spin systems. This made possible that one can perform meaningful simulations within the very restricted computational facilities; all the numerical results presented in this letter were obtained by a DEC Alpha-433 PC in two weeks. These data will not be obtained even by any supercomputer, if one uses the conventional s^z basis. The extension of the condition (10) that the sign problem is removed, and also the application to the higher dimensions are the future problem. In such cases, one should take into account the relevant symmetry that the model possesses as was successful in the present model.
